Abstract

Phase transitions inside the pores of an aerogel are investigated by modeling the aerogel structure by diffusion-limited cluster-cluster aggregation on a cubic lattice in a finite box and considering q -states Potts variables on the empty sites interacting via nearest-neighbours. Using a finite size scaling analysing of Monte-Carlo numerical results, it is concluded that for $q = 4$ the transition changes from first order to second order as the aerogel concentration (density) increases. Comparison is made with the case $q = 3$ (where the first order transition is weaker in three dimensions) and with the case $q = 4$ but for randomly (non correlated) occupied sites. Possible applications to experiments are discussed.

I. INTRODUCTION

In recent time a lot of interest has been driven to the study of phase transitions in porous materials. Number of experiments have been dedicated to study of new features of transitions in helium [1–5] or liquid crystals [6–10] when they are confined within the pores of an aerogel. Theoretical reconstruction of those phenomena has been attempted through various models [11–16].

This paper presents a numerical simulation in three dimensions for a Potts model confined within the pores of a realistic aerogel structure obtained by simulating a diffusion-limited cluster-cluster aggregation (DLCA) process. In spite of its simplicity, the Potts model hides a number of differently behaving models (such as the Ising model, percolation, ...) which can be obtained by a particular choice of the number of states q . In three dimensions it exhibits a first order transition when $q \geq 3$.

The aim of the present article will be to examine how this transition is modified when the studied fluid is confined within pores of an aerogel. Previous studies of the two dimensional Potts model in a randomly diluted medium [17–19] show crossover from first order to second order type behaviour. The same effect was also discussed in more a general context by Berker [20].

Our study will focus on the 4-states Potts model, for which the first order character of the transition is strongly pronounced. Analogous calculations will be performed in two other cases for comparison: $q = 3$ within an aerogel and $q = 4$ within randomly diluted medium.

II. CONSTRAINTS ON THEORY

The Potts model and the aerogel are described here on a $LxLxL$ cubic lattice. The aerogel structure has been obtained by using the diffusion limited cluster-cluster aggregation (DCLA) process with periodic boundary conditions (PBC) [21]. This model is precisely the lattice version of the off-lattice model extensively presented elsewhere [22]. The same lattice

version has been recently extended to investigate numerically the sintering of aerogels [22]. The fraction of sites occupied by the aerogel has been varied from $c = 0.05$ to higher concentrations. In all the configurations used here we have taken care that the aerogel structure is connected in all directions.

On all the remaining free sites of the lattice are positioned q -states Potts variables σ_i which are interacting via nearest-neighbour interactions given by the Hamiltonian:

$$H = -J \sum_{\langle ij \rangle} \delta_{\sigma_i \sigma_j} \quad (1)$$

where δ is the Kronecker symbol. The summation is taken over all the free sites and includes PBC. It has been assumed here that the Potts variables do not interact with the aerogel. Consequently the effect of aerogel is understood as a particular kind of specially correlated dilution with concentration c . This gives the motivation to perform also the calculations in a randomly diluted medium of equal concentration in order to separate the effects of pure disorder from those due to the particular correlations existing in aerogel.

In the present work we have performed Monte-Carlo (MC) simulations by using a simple spin flip Metropolis algorithm. Box sizes of $L=10,12,15$ and 20 have been considered.

The basic quantity that we study and analyse here is the energy probability distribution defined as

$$P_L(E) = \frac{1}{Z_L(K)} N_L(E) \exp(-KE) \quad (2)$$

where $K = J/T$, E is the energy in units of J , $Z_L(K)$ is the partition function and $N_L(E)$ is the total number of configurations with energy E for the system of dimension L . The shape of $P_L(E)$ is different for first or second order phase transitions. A first order transition, in the vicinity of T_c , is characterized by a double peak structure in $P_L(E)$ resulting from the coexistence of the ordered and disordered phases.

The depth of those maxima is related to the interface free energy ΔF between the ordered and disordered phases:

$$\Delta F_L = \ln \frac{P_L(E_M)}{P_L(E_m)} \quad (3)$$

where E_M and E_m denote the energy of one of the maxima and the energy of the minimum of $P_L(E)$, respectively. For a second order transition, on the contrary, $P_L(E)$ exhibits only one maximum. Recently it was shown [24] that a finite size scaling (FSS) analysis of ΔF can be a very efficient tool to detect a first order phase transition, even in the cases where the scaling is performed for sizes lower than the finite correlation length of the first order transition problem. Besides the Binder's fourth order cumulant [25] the study of ΔF scaling has since then been successfully applied to number of problems [26] as a criterion for a first order transition. When the transition is of the first order, the interface energy ΔF_L should scale as L^{d-1} , while otherwise it is expected to disappear with increasing L . The gradual disappearance of the two maxima with increasing concentration and their scaling in L are illustrated on fig.(1) for the case of 4-state Potts model within aerogel of different concentrations. The analysis of ΔF will be given later.

The maxima of $P_L(E)$ are also used to determine the critical temperature. We define by $T_c(c, L)$ the point where the two minima are of equal height. $T_c(c)$ is then obtained by making the extrapolation to infinite L .

Simulations were performed to obtain the best possible guess for T_c (usually closer than 0.01%). Then for close inverse temperatures K' , $P_L(E)$ were found by using the histogram method of Ferenberg and Swendsen [26] based on the formula

$$P_L(E, K') = \frac{P_L(E, K)e^{(K'-K)E}}{\sum_E P_L(E, K)e^{(K'-K)E}} \quad (4)$$

which enabled a more precise determination of T_c , without additional MC runs. The histogram method is very sensitive to the degree of ergodicity achieved. Our simulations have been done with 10^6 - 4×10^6 Monte Carlo flips per spin (MCS). The ergodicity of the results has been examined by calculating also the probability distribution for the different components of the "magnetisation" $P(\alpha, m)$, where m is defined as

$$m(\alpha) = \frac{qM(\alpha) - 1}{q - 1} \quad \alpha = 1, \dots, q \quad (5)$$

and where $M(\alpha) = \langle \sigma(\alpha) \rangle$ is the average of the α -component of the order parameter σ . By comparing $P(\alpha, m)$ for different components one can check if the system has visited all

parts of the phase space. On fig.(2) we present a typical example obtained after $2*10^6$ MCS where the graphs for different components are hardly distinguishable.

More information can be obtained for $P_L(E)$ by calculating higher moments of the energy distribution. The moment of order n is defined as:

$$\langle E^n \rangle_L = \sum_E E^n P_L(E) \quad (6)$$

Here we shall present the results for the specific heat, which has been calculated from

$$C_L(T) = \frac{L^3}{T^2} (\langle E^2 \rangle_L - \langle E \rangle_L^2) \quad (7)$$

The specific heat C_v also exhibits drastically different behaviours in the two cases. For a first order transition C_v behaves as a δ function so that it scales as L^d . For a second order transition it scales as $L^{\alpha/\nu}$, where the α and ν are the specific heat and correlation length critical exponents respectively.

Our study is centered around the $q = 4$ case of the Potts model within the pores of an aerogel. We have chosen $q = 4$ since this model exhibits in the pure case a strong first order transition. For comparison we have also studied two other cases. First is the $q = 3$ case within an aerogel. For $q = 3$ the first order character of the transition is very weak. For illustration, we have reported in fig. (3) $P_L(E)$ at T_c for $q = 3$ and $q = 4$. The aim was to examine how the results would change with changing the number of degrees of freedom of the considered model. Second is the $q = 4$ case with random dilution in the same range of concentrations already discussed. When comparing with the aerogel case, we hope to see the influence of the special short range correlations that exist in aerogels. Before presenting the results, let us stress that the present study is based on simulations made for only a few configurations per given concentration, and no configurational average has been performed. For this reason, the results obtained by the scaling analysis are not expected to give precise quantitative data, especially as it concerns the critical exponents.

III. RESULTS

A. Phase diagram (Critical temperature)

Three sets of results for $T_c(c, L)$ calculated from $P_L(E)$, (as explained in the previous section) are presented in fig. (4). They cover the cases $q = 4$ in aerogel, $q = 4$ with random dilution and $q = 3$ in aerogel.

There we show the data for $L = 15$ and $L = 20$. In all the three cases the data for T_c depend rather weakly on L . Their variations with L are comparable to the error bars which are estimated to be of order 10^{-4} for $c < 0.2$ and 10^{-3} for the higher concentrations presented here. When considering the lower concentrations, the error bars are determined in first place by the precision of the MC procedure and the histogram method which depends on the degree of ergodicity observed. For higher concentrations the configurational fluctuations of disorder are expected to bring the main contribution to the error bars.

Comparing $q = 4$ with $q = 3$ results, both in aerogel, we find that the normalisation of $T_c(c)$ by $T_c(0)$ completely eliminates the difference between the two cases (the dilution has the same effect on our model, independently of the number of degrees of freedom q).

Comparison of the $q = 4$ model in aerogel with the $q = 4$ case with random dilution shows, in contrary, a very clear difference. The fact that T_c for the case with random dilution is lower than T_c in aerogel can be easily understood from geometrical arguments. In the random dilution case a larger number of bonds between Potts spins has been suppressed than in the aerogel case, where all the "dilution" sites are connected. If we neglect the fluctuations, we can try to relate T_c to the effective coordination number $\langle z \rangle$ between Potts sites using the expression

$$\frac{T_c(c)}{T_c(0)} = \frac{\langle z \rangle}{6} \quad (8)$$

For the random dilution case, $\langle z \rangle = 6(1-c)$, which gives a linear dependence on concentration c , illustrated on fig. (4) by the plain line. For aerogel, it can be calculated numerically and gives a nonlinear dependence (presented on the figure by the dashed line). In spite of neglecting the fluctuations, the agreement of numerical data with eq.(8) is surprisingly good.

The largest discrepancy is obtained in aerogel for points between $c = 0.1$ and 0.2 where one expects to find a crossover from first to second order regime.

B. Interface energy

The results for the scaling of the interface free energy are summarized on fig. (5) for the three cases considered above. The precision of the points is at least one order poorer than for T_c .

As it could be concluded from figs. (1a-c), ΔF disappears for $c \geq 0.2$ so that here we present the behaviour for three different concentrations: $c = 0.05, 0.1$ and 0.15 compared to the pure case. The plot of ΔF_L versus L^2 should be a straight line if the transition is of first order. Let us consider first the aerogel $q = 4$ case. As expected, a straight line is obtained for the pure case. A similar behaviour is obtained for $c = 0.05$. For $c = 0.1$ and $c = 0.15$ the results appear to be strongly configuration dependent, fluctuations of disorder becoming important close to the crossover. More intensive calculations implying a larger number of configurations would be needed to determine the exact position of the crossover concentration.

The 4-states case with random dilution shows, even qualitatively, a very similar behaviour than the aerogel case.

For $q = 3$, as already seen on figs. (3), the interface energy is lower, and the effect of disorder seems to manifest itself at lower concentrations. Thus, we can expect the crossover concentration to be dependent of q more than on the type of disorder.

C. Specific heat

The specific heat exhibits a well pronounced maximum, which becomes more broadened as the aerogel concentration increases (fig. (6)). On fig. (7) we try to examine the scaling of C_{Lmax} in the $q = 4$ case in aerogel, on a log-log plot, limited by the fact that, in the case of the specific heat, the data are even less precise than for ΔF , so that at this stage we

expect to obtain only a qualitative idea when comparing various concentrations. The pure case gives the most clear results with a slope very close to 3 as expected for a first order transition. For other concentrations the fluctuations become much more important. One can observe however for $c = 0.05$ a slope still close to 3, while for higher concentrations it becomes much smaller as an indication for a different regime.

IV. DISCUSSION

In the preceding sections we have presented results of Monte Carlo simulations together with a scaling analysis for the Potts model on a cubic lattice either occupied by an aerogel or randomly diluted with the same concentration rates.

In spite of the limitations imposed by the present level of calculations, where no averaging over disorder configurations has been done, we can rise a few points of discussion.

The critical temperature $T_c(c)$ can be rather well approximated by normalizing the pure system critical temperature $T_c(0)$ by the effective coordination number for both cases of disorder. Consequently, there is a clear difference between the phase diagram curves $T_c(c)$ for aerogel and random dilution. It has also been found that there is a nonzero crossover concentration at which the first order transition changes to a second order one, induced by disorder. This change does not seem to be much influenced by the details of dilution (such as correlations), but depends on the number of Potts states q . Question is if the disorder type would remain of so little relevance if we would take into account a more realistic situation where the Potts spins interact with the aerogel.

More intensive calculations, involving averaging over different configurations, would be needed to determine with precision the crossover concentration and calculate the critical exponents in the second order regime. The calculations for the Potts model with random dilution that have previously been performed in two dimensions [17–19] show that critical behaviour in the second order regime is the same as that of the Ising model. Our preliminary results for the specific heat support the thesis that this might be also true in the aerogel

case in three dimensions, but more funded calculations are needed.

V. CONCLUSION

To conclude, we would like to stress that the results of the present calculation are in good qualitative agreement with the general features of most of the existing experiments. In the case of ^4He , it has been observed that the decrease of T_c (compared to the pure case) is more and more pronounced when it is diluted in aerogel, xerogel, and vycor, successively [1]. This is in general agreement with our phase diagram which predicts a monotonic decrease of T_c with increasing aerogel density. Moreover the observed rounded specific heat and the detected second order nature of the phase transition of nCB liquid crystals in a relatively dense aerogel (with density corresponding to $c = 0.16$) [7] are in agreement with our general conclusion for a change from first order to second order above a given crossover aerogel density.

We would like to suggest a systematic series of experiments of phase transitions in the pores of gradually densified aerogels in order to get an explicit experimental variation of the critical temperature with the aerogel density and to detect the existence of the density crossover that we predict here.

Of course the use of the Potts model limits the possibilities of quantitative applications of our results. In the future we intend to use different hamiltonians more specifically adapted to the existing experimental situations.
